Abstract

The objective of this paper was to evaluate the psychometric properties of the *Person Engagement Index* with community dwelling older adults and determine the factors that impact this population's *capacity* to engage in healthcare. This non-experimental pilot evaluation of the psychometrics of the *Person Engagement Index* was performed in a convenience sample of 100 community-dwelling older adults. Exploratory factor analysis was conducted using dimension reduction to determine the underlying structure of a person's capacity to engage in healthcare. Results indicated good internal consistency with Cronbach's $\alpha = .882$ for the overall scale. Exploratory factor analysis with varimax rotation was conducted resulting in a five-factor solution. Four of the five subscales exceeded Cronbach's $\alpha > .70$ threshold for internal consistency. Cronbach's α results for the five domains were: (*Knowledge of Healthcare Status*) = .886, (*Proactive Approach to Healthcare*) = .780, (*Motivation to Manage Healthcare*) = .742, (*Psychosocial Support for Healthcare*) = .658 and (*Technology Use in Healthcare*) = .796. Results suggest that the *Person Engagement Index* instrument is a valid and reliable instrument to measure a person's capacity to engage in healthcare among community dwelling older adults. Testing in different settings with other populations and over time is warranted to further explore the reliability and validity of the *Person Engagement Index* for different subgroups and its sensitivity to changes in health status that may impact a person's capacity to engage in care.

Background

Patient-centered care, a key component of healthcare reform, is critical for improving healthcare outcomes.¹ In order to achieve patient-centered care, it is important to know patients' preferences, wants and needs relevant to their healthcare goals. In addition, effective patient-centered care requires an understanding of the ways in which patients interact with healthcare professionals, healthcare systems and the community. Partnering with patients and their families to be actively engaged in their care is recognized as a significant factor in improving healthcare outcomes.² For example, when patients were involved in their healthcare and quality efforts, outcomes improved.³ Furthermore, knowing that mutual healthcare goal setting is a key component in determining informed

decision-making among patients, families and clinicians, a study found that an instrument focused on measuring what was most important to patients and identifying next steps in their healthcare journey, were critical for moving towards true care partnerships.^{4,5}

The most commonly used instrument to measure patient involvement with their healthcare is the Patient Activation Measure (PAM).⁶ In a study that evaluated the influence of one's activation score, key outcomes included a reduction in average length of stay, increased adherence with healthcare regimens, and better relevant lab results for patients with high cholesterol or diabetes.² Although the 13-item PAM measure is indicative of one's involvement in their care, other factors are critical to evaluate a person's *capacity* to be engaged in that care.

In order to support the ability of clinicians to practice within a patient-centered model and partner with patients in their care, an instrument to assess a person's capacity to engage in his or her care was an identified need to assist people with engaging in their care journey. As a result, the *Person Engagement Index* instrument was developed to measure a person's capacity to engage in their healthcare.

The health and healthcare needs of older adults increase in complexity as one ages. Older adults are more likely to have a chronic condition or multiple co-morbidities and be on multiple medications,⁷ requiring even greater engagement on the part of the older adult and the healthcare team. This complexity, coupled with complications associated with the natural aging process (e.g., cognitive decline, changes in eyesight, hearing loss and higher risk of depression) requires an even greater understanding of older adults' capacity to engage with the healthcare professionals who serve them⁸. Thus, older adults were selected as the focus for initial testing of the psychometric properties of the *Person Engagement Index* to assess their capacity for engagement. Therefore, the purpose of this initial exploratory pilot study was to evaluate the psychometric properties of the *Person Engagement Index* in a sample of community-dwelling older adults.

Instrument Development

The conceptual framework for this exploratory pilot study was the Interactive Care Model™ (ICM), a five phase care delivery process model for better engaging people in their care. The assessment phase of the model is the focus for the development of this instrument to measure a person's capacity to engage in their healthcare.⁹ In a comprehensive review of the literature, which explored the following databases: CINAHL Complete, MEDLINE Complete, Mental Measurements, PUBMED and SocINDEX, it was found that in addition to a patient's level of activation, seven other factors that can influence a person's capacity to engage were identified. The eight factors include: 1) patient preferences, values, and needs; 2) activation /motivation; 3) health literacy; 4) disease burden; 5) preventative measures; 6) psychosocial components; 7) technology use in healthcare and; 8) involvement in healthcare safety.^{1,2,4,10-14} Several of these factors had measurement instruments focused on the specific domain only and not in a combined scale to measure a person's capacity to engage in their healthcare.^{1,6,13,15-21}

The combined information from review of the literature and expert consultation was used to develop five items for each of the eight domains to measure a person's capacity to engage in their healthcare. The 40 original items underwent expert review by eight members of a multidisciplinary Clinical Advisory Council. This interprofessional pool of content experts included nursing

leaders with expertise in patient engagement in academia, practice, and research, and leaders in patient engagement and education in medicine and pharmacy. Content validation was conducted using item-content validity index (I-CVI) of the original 40 items, on a relevancy scale of one to four where, 1=no relevancy, 2=somewhat relevant, 3=quite relevant and 4=highly relevant.²² I-CVI scores of .78 or higher were considered relevant to the capacity to engage in healthcare construct being measured. Eleven of the original 40 items were below the I-CVI threshold and considered for deletion. The items deleted had I-CVI scores of ranging from .625-.75. Based on the scores for item content validation, expert feedback, and the importance of the item to the overall study objectives, the *Person Engagement Index* was revised to include 24 items (three per domain) to test in this exploratory pilot study.

Methods

Participants

Institutional Review Board (IRB) approval was obtained for this study. Participants were obtained from a convenience sample of 100 community-dwelling older participants (65 years of age and older) of an existing IRB-approved research registry maintained by the University Center for Social and Urban Research (UCSUR) who agreed to complete the telephone survey. Participants were recruited from a variety of population-based surveys conducted by UCSUR (*Refer to Table 1 for registry characteristics*). Table 1 demonstrates UCSUR Registry participants' adequate variation in the social-behavioral characteristics of interest; 39% of registry participants are at least 65 years of age and 19% of the older adults display evidence of low health literacy.

Instrument

The *Person Engagement Index* uses a 5-point Likert Scale: strongly disagree = 1; disagree = 2; neither agree nor disagree = 3; agree = 4; and strongly agree = 5. A higher rating indicates a greater capacity to engage in one's healthcare. Readability of the instrument items included examination of the Flesh-Kincaid Grade level = 7.4 and the Flesh Reading Ease = 70.4/100.²² Items were dispersed throughout the survey for each of the domains. Subscales were scored by summing Likert scored items (range: 1-5) within each respective subscale and subsequently normalized using min-max scaling.

Procedures

Following informed consent, participants were verbally interviewed by phone by a trained survey administrative professional. The instrument is designed to be administered electronically, paper and pencil or verbally over the phone by a trained survey administrative professional. Phone interviews were an average of 15 minutes long.

Table 1: Characteristics of UCSUR Registry Participants (n=1000)

Non-white race	10%
Non-English speaking	3%
Low education \leq high school	33%
Low income \leq \$25K	24%
Uninsured	7%
Poor overall health	19%
Low health literacy	19%
Sub-group \geq 65 years (n=395)	39%
Require help reading instructions	13%
Difficulty understanding written	11%
Difficulty completing forms	27%

Statistical Analysis

All analyses were performed using SPSS (version 21.0, IBM, Inc., Chicago, IL). Appropriate descriptive statistics (mean, standard deviation, median, range, frequency and percentage) were used to summarize participant characteristics. To investigate interrelationships and possible clustering among items, Pearson correlation coefficients were used. An exploratory factor analysis (EFA) with principal axis factoring (PCA) extraction and orthogonal varimax rotation was used to explore the underlying structure of the scale.

A Kaiser-Meyer-Olkin value of ≥ 0.80 was used to indicate an adequate sample and a significant Bartlett's test was used to indicate appropriateness of PCA. In the PCA solution, the scree test and total variance explained were examined to determine the number of underlying factors in the *Person Engagement Index* scale. Factors with eigenvalues greater than 1.0 were extracted. In the extraction phase, items that met a minimum factor loading of .40 were considered relevant. Two items loaded on more than one factor but given factor loading differences of $< .2$, a decision was made to restrict each item to the factor with higher loading. If the items did not load on any factor at the cut-off of $> .40$, the item was flagged for further investigation.

Subscales were interpreted and labeled by the research team based on identified factors using this EFA approach. Lastly, internal consistency of subscales was assessed using Cronbach's alpha coefficient, a reliability index that estimates the internal consistency of the items in the instrument. Alpha coefficients and item-total correlations were examined. An alpha coefficient of .70 or higher was considered to be acceptable.

Results

Sample Characteristics

The mean age of the respondents was 75 years old. For sample characteristics of age, gender, marital status, race, educational level, employment status and annual income, please refer to Table 2.

Item Characteristics

The overall total scale mean score was 4.14, indicating a high level of capacity for engaging in one's healthcare among this sample of community-dwelling older adults. Item means ranged from 3.17 to 4.39. The item with the lowest mean score was: *It is a challenge to participate in activities that would improve my health, due to my health problems* and the item with the highest mean score was: *When something seems "not right" to me in my healthcare, I speak up to my doctor, nurse, care team members or family*. The domain subscale mean scores ranged from 3.63 to 4.29. The domain with the highest mean score was *Knowledge about Healthcare Status* and the lowest mean score was the *Technology Use in Healthcare* domain. (Refer to Table 3 for item characteristics). During survey administration, none of the older adults surveyed expressed any misunderstanding or requested further explanation of the questions, indicating that the respondents had a good understanding of the questions posed.

Descriptive Statistics Between Factor Correlations and Cronbach's Alpha Coefficients

Table 4 presents the descriptive statistics between factor correlations and Cronbach's alpha coefficients for the five generated subscales (corresponding to Factors I to V). Internal consistency ranged from .658 to .886. All *Person Engagement Index* subscales demonstrated good internal consistency. The correlations among the subscales ranged from .272 to .658 (Refer to Table 4 for factor correlations). The item-total correlations were good for all items within the subscales: *Knowledge of Healthcare Status* (.425 to .627), *Proactive Approach to Healthcare* (.297 to .652), *Motivation to*

Manage Healthcare (.220 to .580), Psychosocial Support for Healthcare (.069 to .584) and Technology Use in Healthcare (.490 to .623).

Reliability

Results indicated good internal consistency for the overall scale with Cronbach's alpha = .882. Four of the five subscales exceeded Cronbach's alpha > .70 threshold for internal consistency of the instrument. Cronbach's alpha results for the five domains were: Factor I (*Knowledge of Healthcare Status*) = .886; Factor II (*Proactive Approach to Healthcare*) = .780; Factor III (*Motivation to Manage Healthcare*) = .742; Factor IV (*Psychosocial Support for Healthcare*) = .658; and Factor V (*Technology Use in Healthcare*) = .796. After an examination of total item correlations and Cronbach's alpha change if an item is deleted for the total scale, five item correlations were below the .40 threshold, ranging from .094 to .392. Three of these items would have increased reliability for the overall scale, if removed from

the scale: *I rely heavily on others to assist me with my health problems*, would increase Cronbach's alpha to .888; *It is a challenge to participate in activities that would improve my health, due to my health problems* would increase Cronbach's alpha to .886; and *I have limited ability to participate in managing my health, due to my health problems* would increase Cronbach's alpha to .883.

Construct Validity: Factor Loadings

The initial unrotated principal components analysis included six components extracted with eigenvalues greater than 1.0 and commonalities ranging from .466 to .783. After examination of the scree plot and percent variance explained by the component, it was determined a five factor solution was supported. The sixth component had an eigenvalue greater than 1; however, it had less than 5% contribution to the overall percent variance explained (4.5%), supporting the five-factor solution.^{23,24} PCA with varimax rotation was conducted for a five-factor solution.

Table 3. Item Characteristics of the 24-item Person Engagement Index Scale (N= 100)

Item	Mean (SD)	Median (IQR)	% of Min Scores (1-2)	% of Max Scores (4-5)
1. I am motivated to take charge of my healthcare.	4.36 (0.78)	4 (1)	3.0	93.0
2. I have all the information I need to make an informed decision about my healthcare.	4.05 (0.83)	4 (1)	8.0	87.0
3. My healthcare goals are based on what is most important to me.	4.38 (0.62)	4 (1)	1.0	45.0
4. I have people in my life that I know I can rely on if I need help taking care of my health.	4.28 (0.85)	4 (1)	7.0	91.0
5. When something seems “not right” to me in my healthcare, I speak up to my doctor, nurse, care team members or family.	4.39 (0.76)	5 (1)	5.0	93.0
6. I think that technology (i.e., computers, cellphones, email, texting, video chat, etc.) either has or could be a good tool to help better manage my health.	3.86 (1.04)	4 (1)	17.0	69.0
7. I take actions to make sure I am the healthiest I can be.	4.15 (0.80)	4 (1)	13.0	87.0
8. I rely heavily on others to assist me with my health problems.	3.94 (0.98)	4 (1)	14.0	81.0
9. My health is a priority in my life	4.20 (0.85)	4 (1)	7.0	86.0
10. I understand what my healthcare choices are after speaking with my doctor, nurse or care team members.	4.27 (0.65)	4 (1)	3.0	95.0
11. I discuss my healthcare goals with my doctor, nurse or other members of my care team.	4.12 (0.79)	4 (1)	7.0	88.0
12. I am able to access healthcare for prevention and illness when I need it.	4.37 (0.60)	4 (1)	2.0	98.0
13. When I am concerned about my care, I tell my doctor, nurse or care team members or family about the concern I have.	4.34 (0.59)	4 (1)	1.0	96.0
14. I am open to receiving some of my healthcare through technology (i.e., computers, cellphones, email, texting, video chat, etc.).	3.66 (1.16)	4 (1)	22.0	69.0
15. If I have a concern about my health, I take action to address it.	4.31 (0.65)	4 (1)	3.0	96.0
16. I have limited ability to participate in managing my health, due to my health problems.	3.93 (1.11)	4 (1)	16.0	82.0
17. When I have a health concern, I want to learn more about it.	4.36 (0.58)	4 (1)	1.0	97.0
18. I can tell others what is going on with my health.	4.26 (0.60)	4 (1)	1.0	94.0
19. I see myself as part of my healthcare team that establishes goals that matter to me.	4.38 (0.55)	4 (1)	1.0	98.0
20. I have the necessary support from friends and family in my life to achieve my health goals.	4.10 (0.79)	4 (1)	7.0	89.0
21. I tell my doctors, nurses, care team or family members when my healthcare may not be what I think I need.	4.18 (0.77)	4 (1)	6.0	90.0
22. I have the capability to use technology (i.e., computers, cellphones, email, texting, video chat, etc.) to assist me with my healthcare.	3.55 (1.15)	4 (1)	24.0	68.0
23. I engage in activities to maintain my health.	4.02 (0.89)	4 (1)	11.0	83.0
24. It is a challenge to participate in activities that would improve my health, due to my health problems.	3.18 (1.24)	4 (2)	37.0	52.0

PCA with promax rotation to compare interpretability of the solution was conducted and did not improve the solution interpretability. Thus, varimax rotation was retained for the analysis.

After varimax rotation, the first component accounted for 32.5% of the total variance; the second component, 10.1%; the third component 7.3%; fourth component, 6.1%; and the fifth component, 5.7%. The five factors accounted for 61.7% of the total variance. The first

Table 4. Internal Consistency and Factor Correlations of the Person Engagement Index Subscales (N= 100)

Factors subscales	Cronbach's alpha	Mean (SD)	Median (Range, IQR)	Factor			
				I	II	III	IV
Factor I: Knowledge of Healthcare status	0.886	82.13 (12.08)	78.13 (50.00-100, 18.75)				
Factor II: Proactive Approach to Healthcare	0.780	82.06 (13.98)	81.25 (25.00-100, 18.75)	.658			
Factor III: Motivation to Manage Healthcare	0.742	79.50 (15.64)	81.25 (25.00-100, 25.00)	.482	.450		
Factor IV: Psychosocial Support for Healthcare	0.658	72.30 (16.38)	75.00 (20.00-100, 20.00)	.272	.249	.266	
Factor V: Technology Use in Healthcare	0.796	65.83 (23.59)	75.00 (8.33-100, 33.33)	.362	.372	.360	.371

Note. *IQR* Interquartile range; Higher numbers indicates higher capacity to engage. Subscale means based on normalized subscale scores

component included eight of the 24 items, the second and third components each had four items, the fourth component had five items and the final component had three items. All loadings met the threshold of .40, ranging from .432 to .838. Two items had similar magnitude loadings on two components: *I engage in activities to maintain my health*, .470 and .432 (component 3 and component 4, respectively), and *When I am concerned about my care, I tell my doctor, nurse or care team members or family about the concern*, .554 and .526 (component 1 and 2, respectively). Since the difference in the loadings on each factor was greater than .20, the item was assigned to the factor with the higher loading. The first factor was labeled *Knowledge of Healthcare Status*, the second factor was labeled *Proactive Approach to Healthcare*, the third factor was labeled *Motivation to Manage Healthcare*, the fourth factor was labeled *Psychosocial Support for Healthcare* and the fifth factor was labeled *Technology Use in Healthcare* (Refer to Table 5 for item varimax rotated factor loading principle component analysis).

Discussion

The initial *Person Engagement Index* proposed eight domains. However, after exploratory factor analysis, five factors were extracted to explain the construct of a person's capacity to engage in their healthcare: Factor I (*Knowledge of Healthcare Status*), Factor II (*Proactive Approach to Healthcare*), Factor III (*Motivation to Manage Healthcare*), Factor IV (*Psychosocial Support for Healthcare*) and Factor V (*Technology Use in Healthcare*).

Results suggest that the *Person Engagement Index* is a valid and reliable instrument to measure the capacity to engage in healthcare among community-dwelling older adults. However, the *Psychosocial Support* domain's reliability, Cronbach's alpha=.658, was less than the .70 threshold, which contains the three items discussed that would

improve the scale's reliability, along with two other items. With elimination of these three items, Cronbach's alpha of the *Psychosocial Support* domain would increase to .736. Further testing is needed without these three items, which were part of the original disease burden domain.

This pilot study contributes to the research that supports the importance in considering a person's capacity to engage in their healthcare. Results of this pilot study are promising, however, further investigation is needed in a larger sample to test for reliable use in practice. Potential implications for use of the *Person Engagement Index* are discussed. Knowing a person's capacity to engage in their healthcare has the potential to assist with targeting areas of support needed to help people be better engaged in their care. This instrument was designed with the intent to be used among different populations to evaluate a person's capacity to engage in care at each encounter with the healthcare system, as well as ongoing evaluation of self-care management. This was an exploratory pilot study to test the items among older community dwelling adults; further testing among various populations and settings is warranted. Future evaluation will determine if the use of the *Person Engagement Index* can help guide timely interventions that can potentially be implemented to assist people with self-care management. In addition, use of the instrument in education among interprofessional clinicians has the potential ability to help guide the direction of the care process, as well as engage people at the onset of their care to include them as partners in the plan based on their assessment.

Limitations

Limitations of this study include the sample size. Although exploratory in nature and meeting sampling adequacy criteria for this pilot study, these results should be

Table 5. Varimax Rotated Factor Loadings, Principal Component Analysis of the Person Engagement Index Scale Items (N=100)

Item	Factor				
	I	II	III	IV	V

Cumulative Percent of Variance	32.5	42.6	49.9	56.0	61.7
Cronbach’s alpha =.882 (overall scale)	.886	.780	.742	.658	.796

interpreted with caution due to the sample size of 100. Nunnally recommends 10 cases per item for testing an instrument to measure the underlying construct; in this case, a sample of 240 is recommended.²⁵ This pilot study included community-dwelling older adults only, limiting the generalizability of the results to other populations. Due to the construct being measured, testing in different

settings and among other populations is warranted to account for health status changes that may impact a person’s capacity to engage in their healthcare. Furthermore, social desirability response bias could be a factor in the results due to the construct being measured and the fact that questionnaire was delivered orally over the phone.

Conclusion

Further testing of the *Person Engagement Index* is suggested to determine if the reduction in items, tested among various populations, in and out of various healthcare and community settings, results in acceptable psychometric properties to measure the construct of a person's capacity to engage in their healthcare. In addition, although this exploratory pilot study results are encouraging, the testing of the use of the instrument in practice in larger studies is needed. As patient engagement efforts continue to evolve and care delivery models emerge to create a true clinician and patient partnership for care, the *Person Engagement Index* has the potential to be used as an assessment instrument with the intent to help better engage people in healthcare based on their assessment results. It is hypothesized that knowing a person's capacity to be engaged in their healthcare and tailoring interventions, resources and support accordingly, can potentially assist with developing practical strategies to improve the patient experience across the care continuum and enhance self-care management.
